

# Renamingless Capture-Avoiding Substitution for Definitional Interpreters

Casper Bach Poulsen   

Delft University of Technology, Netherlands

## Abstract

Substitution is a common and popular approach to implementing name binding in definitional interpreters. A common pitfall of implementing substitution functions is *variable capture*. The traditional approach to avoiding variable capture is to rename variables. However, traditional renaming makes for an inefficient interpretation strategy. Furthermore, for applications where partially-interpreted terms are user facing it can be confusing if names in uninterpreted parts of the program have been changed. In this paper we explore two techniques for implementing capture avoiding substitution in definitional interpreters in a way that avoids renaming.

## 1 Introduction

Following Reynolds [21], a definitional interpreter is an important and frequently used method of defining a programming language, by giving an interpreter for the language that is written in a second, hopefully better understood language. The method is widely used both for programming language research [3, 4, 13, 18, 22] and teaching [15, 19, 23]. A commonly used approach to defining name binding in such interpreters is *substitution*. A key stumbling block when implementing substitution is how to deal with *name capture*. The issue is illustrated by the following untyped  $\lambda$  term:

$$(\lambda f. \lambda y. (f\ 1) + y) (\lambda z. \underbrace{y}_{\text{free variable}}) 2 \quad (1)$$

This term does *not* evaluate to a number value because  $y$  is a *free variable*; i.e., it is not bound by an enclosing  $\lambda$  term. However, using a naïve, non capture avoiding substitution strategy to normalize the term would cause  $f$  to be substituted to yield an interpreter state corresponding to the following (wrong) intermediate term  $(\lambda y. ((\lambda z. y) 1) + y) 2$  where the red  $y$  is *captured*; that is, it is no longer a free variable.

Following, e.g., Curry and Feys [12], Plotkin [20], or Barendregt [5], the common technique to avoid such name capture is to *rename* variables either before or during substitution (a process known as  $\alpha$ -conversion [11]). For example, by renaming the  $\lambda$  bound variable  $y$  to  $r$ , we can correctly reduce term (1) to  $(\lambda r. ((\lambda z. r) 1) + r) 2$ .

While a renaming based substitution strategy provides a well behaved and versatile approach to avoiding name capture, it has some trade-offs. For example, since renaming typically works by fully traversing terms, definitional interpreters that use renaming based substitution are typically relatively slow. Another trade-off is that renaming gives rise to intermediate terms whose names differ from the names in source programs. For applications where intermediate terms are user facing (e.g., in error messages, or in systems based on rewriting) this can be confusing. For this reason, definitional interpreters often use alternative techniques for (lazy) capture avoiding substitution, such as *closures* [16], *de*

44 *Bruijn indices* [14], *explicit substitutions* [1], or *locally nameless* [9]. However, traditional  
 45 named variable substitution is sometimes preferred because intermediate terms are easy to  
 46 inspect and compare. This paper considers and explores named substitution strategies that  
 47 do not rely on renaming variables. We explore two possible solutions to this problem, neither  
 48 of which seem to be widely known or at least not widely used.

49 The first technique we explore is a technique that Eelco Visser and I were using to teach  
 50 students about static scoping, by having students implement definitional interpreters. To  
 51 this end, we used a simple renamingless substitution strategy which (for applications that do  
 52 not perform evaluation under binders) is capture avoiding. The idea is to delimit and never  
 53 substitute into those terms in abstract syntax trees (ASTs) where all substitutions that were  
 54 supposed to be applied to the term, have been applied; e.g., terms that have been computed  
 55 to normal form. For example, using `|` and `|` for this delimiter, an intermediate reduct of the  
 56 term labeled (1) above is  $(\lambda y. (|(\lambda z. y)| 1) + y) 2$ . Here the delimited **highlighted** term is  
 57 closed under substitution, such that the substitution of  $y$  for  $2$  is not propagated past the  
 58 delimiter; i.e., using  $\rightsquigarrow$  to denote step-wise evaluation:

$$\begin{aligned}
 & (\lambda f. \lambda y. (f\ 1) + y) (\lambda z. y) 2 \\
 \rightsquigarrow & (\lambda y. (|(\lambda z. y)| 1) + y) 2 \\
 \rightsquigarrow & (|(\lambda z. y)| 1) + 2 \\
 \rightsquigarrow & ((\lambda z. y) 1) + 2 \\
 \rightsquigarrow & y + 2
 \end{aligned}$$

65 The result term computed by these reduction steps is equivalent to using a renaming based  
 66 substitution function. However, the renamingless substitution strategy we used does not  
 67 rename variables (and so preserves the names of bound variables in programs), is simple to  
 68 implement, and is more efficient than interpreters that rename variables at run time.

69 I never had the chance to discuss the novelty of the technique with Eelco. However, the  
 70 technique we used in the course does not seem widely known or used. In this paper we  
 71 explain and explore the technique and its limitations. The main known limitation of using  
 72 the technique for defining interpreters is that it assumes an interpretation strategy that does  
 73 not do evaluation under binders. For the toy language interpreters we used for teaching this  
 74 was not a problem; for more serious languages and applications it may be.

75 The second technique for capture-avoiding named substitution that we explore is an  
 76 existing technique which we were made aware of by a reviewer of a previous version of this  
 77 paper. The technique is due to Berkling and Fehr [7] and has similar benefits as the technique  
 78 we used in our course: it does not rename variables and is also more efficient than interpreters  
 79 that rename variables at run time. Furthermore, the technique does not make assumptions  
 80 on behalf of interpretation strategy, and it supports evaluation under binders. On the other  
 81 hand, Berkling and Fehr's substitution technique is more involved to implement and is a  
 82 little less efficient than the renamingless substitution strategy that we used in our course.

83 The renamingless techniques we consider in this paper are not new (at least the second  
 84 technique is not; we do not expect that the first one is either, though we have not found it in  
 85 the literature). But we believe they deserve to be more widely known. Our contributions are:

- 86 ■ We describe (§ 2) a simple, renamingless substitution technique for languages with  
 87 open terms where evaluation does not happen under binders. The meta-theory of this  
 88 technique is left for future work, but we discuss and illustrate known limitations in terms  
 89 of examples.
- 90 ■ We describe (§ 3) an existing and more general technique [7] which has similar benefits

and does not suffer from the same limitations. However, its implementation is a little more involved to implement than the simple renamingless substitution strategy, and it is a little less efficient.

This paper is a literate Haskell document, available at <https://github.com/casperbp/renamingless-capture-avoiding>, and is structured as follows. § 2 describes a simple renamingless capture avoiding substitution strategy and its known limitations and § 3 describes Berkling-Fehr substitution which has similar benefits and fewer limitations but is less simple to implement. § 4 discusses related work and § 5 concludes.

## 2 Renamingless Capture-Avoiding Substitution

We present a simple technique for capture avoiding substitution, which avoids the need to rename bound variables. To demonstrate that the technique is about as simple to implement as substitution for closed terms (i.e., terms with no free variables, for which variable capture is not a problem), we first implement a standard substitution-based definitional interpreter for a language with closed, call-by-value  $\lambda$  expressions.

### 2.1 Interpreting Closed Expressions

Below left is a data type for the abstract syntax of a language with  $\lambda$ s, variables, applications, and numbers. On the right is the substitution function for the language. The function binds three parameters: (1) the variable name (*String*) to be substituted, (2) the expression the name should be replaced by, and (3) the expression in which substitution happens.

<b>data</b> <i>Expr</i> <sub>0</sub>	<i>subst</i> <sub>0</sub> :: <i>String</i> → <i>Expr</i> <sub>0</sub> → <i>Expr</i> <sub>0</sub> → <i>Expr</i> <sub>0</sub>
= <i>Lam</i> <sub>0</sub> <i>String Expr</i> <sub>0</sub>	<i>subst</i> <sub>0</sub> <i>x s</i> ( <i>Lam</i> <sub>0</sub> <i>y e</i> )   <i>x</i> ≡ <i>y</i> = <i>Lam</i> <sub>0</sub> <i>y e</i>
<i>Var</i> <sub>0</sub> <i>String</i>	<i>otherwise</i> = <i>Lam</i> <sub>0</sub> <i>y</i> ( <i>subst</i> <sub>0</sub> <i>x s e</i> )
<i>App</i> <sub>0</sub> <i>Expr</i> <sub>0</sub> <i>Expr</i> <sub>0</sub>	<i>subst</i> <sub>0</sub> <i>x s</i> ( <i>Var</i> <sub>0</sub> <i>y</i> )   <i>x</i> ≡ <i>y</i> = <i>s</i>
<i>Num</i> <sub>0</sub> <i>Int</i>	<i>otherwise</i> = <i>Var</i> <sub>0</sub> <i>y</i>
	<i>subst</i> <sub>0</sub> <i>x s</i> ( <i>App</i> <sub>0</sub> <i>e</i> <sub>1</sub> <i>e</i> <sub>2</sub> ) = <i>App</i> <sub>0</sub> ( <i>subst</i> <sub>0</sub> <i>x s e</i> <sub>1</sub> ) ( <i>subst</i> <sub>0</sub> <i>x s e</i> <sub>2</sub> )
	<i>subst</i> <sub>0</sub> – ( <i>Num</i> <sub>0</sub> <i>z</i> ) = <i>Num</i> <sub>0</sub> <i>z</i>

The main interesting case is the case for *Lam*<sub>0</sub>. There are two sub-cases, declared using *guards* (the Boolean expressions after the vertical bar). The first sub-case is when the variable being substituted matches the bound variable (*x* ≡ *y*). Since the inner variable shadows the outer, the substitution is not propagated into the body. In the other case (*otherwise*), the substitution is propagated. This other case relies on an implicit assumption that the expression being substituted by *x* does not have *y* as a free variable. If we violate this assumption, the substitution function and interpreter *interp*<sub>0</sub> on the left below is not going to be capture avoiding. Below right is an example invocation of the interpreter.

<i>interp</i> <sub>0</sub> :: <i>Expr</i> <sub>0</sub> → <i>Expr</i> <sub>0</sub>	
<i>interp</i> <sub>0</sub> ( <i>Lam</i> <sub>0</sub> <i>x e</i> ) = <i>Lam</i> <sub>0</sub> <i>x e</i>	
<i>interp</i> <sub>0</sub> ( <i>Var</i> <sub>0</sub> –) = <i>error</i> "Free variable"	> <i>interp</i> <sub>0</sub> ( <i>App</i> <sub>0</sub> ( <i>Lam</i> <sub>0</sub> "x" ( <i>Var</i> <sub>0</sub> "x"))
<i>interp</i> <sub>0</sub> ( <i>App</i> <sub>0</sub> <i>e</i> <sub>1</sub> <i>e</i> <sub>2</sub> ) = <b>case</b> <i>interp</i> <sub>0</sub> <i>e</i> <sub>1</sub> <b>of</b>	( <i>Num</i> <sub>0</sub> 42))
<i>Lam</i> <sub>0</sub> <i>x e</i> → <i>interp</i> <sub>0</sub> ( <i>subst</i> <sub>0</sub> <i>x</i> ( <i>interp</i> <sub>0</sub> <i>e</i> <sub>2</sub> ) <i>e</i> )	<i>Num</i> <sub>0</sub> 42
– → <i>error</i> "Bad application"	
<i>interp</i> <sub>0</sub> ( <i>Num</i> <sub>0</sub> <i>z</i> ) = <i>Num</i> <sub>0</sub> <i>z</i>	

## 2.2 Intermezzo: Capture-Avoiding Substitution Using Renaming

The substitution function  $subst_0$  relies on an implicit assumption that expressions are closed; i.e., do not contain free variables. If we want to support *open expressions* (i.e., expressions that may contain free variables), we must take care to avoid variable capture. A traditional approach [20] is to rename variables during interpretation. Let  $subst_{01}$  be a function whose cases are the same as  $subst_0$ , except for the  $Lam_0$  case:

$$\begin{aligned} subst_{01} \ x \ s \ (Lam_0 \ y \ e) \mid x \equiv y &= Lam_0 \ y \ e \\ \mid otherwise &= \text{let } z = \text{fresh } x \ y \ s \ e \\ &\text{in } Lam_0 \ z \ (subst_{01} \ x \ s \ (subst_{01} \ y \ (Var_0 \ z) \ e)) \end{aligned}$$

Here  $\text{fresh } x \ y \ s \ e$  is a function that returns a fresh identifier if  $x \notin FV(e)$  or  $y \notin FV(s)$ , or returns  $y$  otherwise. While this renaming based substitution strategy provides a relatively conceptually straightforward solution to the name capture problem, it requires an approach to generating fresh variables, and, since it performs two recursive calls to  $subst_{01}$ , it is inherently less efficient than the substitution function from § 2.1—even in a lazy language like Haskell. Furthermore, depending on how  $\text{fresh}$  is implemented, the interpreter may not preserve the names of  $\lambda$ -bound variables. In the next section we introduce a simple alternative substitution strategy which does not rename or generate fresh variables, and which has similar efficiency as substitution for closed expressions. The substitution strategy is capture-avoiding for languages that do not evaluate under binders.

## 2.3 Interpreting Open Expressions with Renamingless Substitution

Let us revisit the interpretation function  $interp_0$  from § 2.1. Because our interpreter eagerly applies substitutions whenever it can, and because evaluation always happens at the top-level, never under binders, we know the following. Whenever the interpreter reaches an application expression  $e_1 \ e_2$ , we know that *any variable that occurs free in  $e_2$  corresponds to a variable that was free to begin with*. The same goes for the expressions resulting from interpreting  $e_2$ . We can exploit this knowledge in our interpreter and substitution function. To this end, we introduce a dedicated expression form (the highlighted  $Clo_1$  constructor below) which delimits expressions that have been closed under substitutions such that we never propagate substitutions past this closure delimiter:

$\begin{aligned} \text{data } Expr_1 & \\ &= Lam_1 \ String \ Expr_1 \\ &\mid Var_1 \ String \\ &\mid App_1 \ Expr_1 \ Expr_1 \\ &\mid Num_1 \ Int \\ &\mid Clo_1 \ Expr_1 \end{aligned}$	$\begin{aligned} subst_1 &:: String \rightarrow Expr_1 \rightarrow Expr_1 \rightarrow Expr_1 \\ subst_1 \ x \ s \ (Lam_1 \ y \ e) \mid x \equiv y &= Lam_1 \ y \ e \\ \mid otherwise &= Lam_1 \ y \ (subst_1 \ x \ s \ e) \\ subst_1 \ x \ s \ (Var_1 \ y) \mid x \equiv y &= s \\ \mid otherwise &= Var_1 \ y \\ subst_1 \ x \ s \ (App_1 \ e_1 \ e_2) &= App_1 \ (subst_1 \ x \ s \ e_1) \ (subst_1 \ x \ s \ e_2) \\ subst_1 \ _ \ _ \ (Num_1 \ z) &= Num_1 \ z \\ subst_1 \ _ \ _ \ (Clo_1 \ e) &= Clo_1 \ e \end{aligned}$
---	---

Here  $subst_1$  does not propagate substitutions into expressions delimited by  $Clo_1$ . The interpretation function  $interp_1$  uses  $Clo_1$  to close expressions before substituting (in the  $App_1$  case), thereby avoiding name capture:

$$\begin{aligned} interp_1 &:: Expr_1 \rightarrow Expr_1 \\ interp_1 \ (Lam_1 \ x \ e) &= Lam_1 \ x \ e \\ interp_1 \ (Var_1 \ x) &= Var_1 \ x \end{aligned}$$

```

156   $interp_1 (App_1 e_1 e_2) = \text{case } interp_1 e_1 \text{ of}$ 
157     $Lam_1 x e \rightarrow interp_1 (subst_1 x (Clo_1 (interp_1 e_2)) e)$ 
158     $e'_1 \rightarrow App_1 e'_1 (interp_1 e_2)$ 
159   $interp_1 (Num_1 z) = Num_1 z$ 
160   $interp_1 (Clo_1 e) = e$ 

```

Whereas  $interp_0$  explicitly crashes when encountering a free variable or when attempting to apply a non-function to a number,  $interp_1$  may return a “stuck” term in case it encounters a free variable or an application expression that attempts to apply a value other than a function. The last case of  $interp_1$  says that, when the interpreter encounters a closed expression, it “unpacks” the closure. This unpacking will not cause accidental capture: because interpretation only happens at the top-level, never under binders, unpacking can never cause variable capture!

To illustrate how  $interp_1$  works, let us consider how to interpret  $((\lambda f. \lambda y. f\ 0) (\lambda z. y)\ 1)$ . The rewrites below informally illustrate the interpretation process, where for brevity we use  $\lambda$  notation instead of the corresponding constructors in Haskell and  $[e]$  instead of  $Clo_1\ e$ :

```

171   $interp_1 ((\lambda f. \lambda y. f\ 0) (\lambda z. y)\ 1)$ 
172   $\equiv interp_1 ((\lambda y. [(\lambda z. y)]\ 0)\ 1)$ 
173   $\equiv interp_1 ([(\lambda z. y)]\ 0)$ 
174   $\equiv y$ 
175

```

Unlike the renaming based substitution strategy discussed in § 2.2, our renamingless substitution strategy does not require renaming or generating fresh variables. Its efficiency is similar as substitution for closed expressions. It also preserves the names of binders. However, the renamingless substitution strategy in  $subst_1$  and  $interp_1$  relies on an assumption that evaluation does not happen under binders.

## 2.4 Limitation: Renamingless Substitution Does Not Support Evaluation Under Binders

The renamingless substitution strategy from § 2.3 assumes that the terms being closed have been closed under *all substitutions of variables bound in the context*. Interpretation strategies that evaluate under binders violate this assumption. For example, consider the interpreter given by  $normalize_1$  whose highlighted recursive call performs evaluation under a  $\lambda$  binder:

```

187   $normalize_1 :: Expr_1 \rightarrow Expr_1$ 
188   $normalize_1 (Lam_1 x e) = Lam_1 x (normalize_1 e)$ 
189   $normalize_1 (Var_1 x) = Var_1 x$ 
190   $normalize_1 (App_1 e_1 e_2) = \text{case } normalize_1 e_1 \text{ of}$ 
191     $Lam_1 x e \rightarrow normalize_1 (subst_1 x (Clo_1 (normalize_1 e_2)) e)$ 
192     $e'_1 \rightarrow App_1 e'_1 (normalize_1 e_2)$ 
193   $normalize_1 (Num_1 z) = Num_1 z$ 
194   $normalize_1 (Clo_1 e) = e$ 

```

Just like  $interp_1$ , the  $normalize_1$  function closes off terms before substituting. However, because  $normalize_1$  evaluates under  $\lambda$  binders, closures may be prematurely unpacked, which may result in variable capture. For example, say we apply  $(\lambda x. \lambda y. x)$  to the free variable

198  $y$ . We would expect the result of evaluating this application to contain  $y$  as a free variable.  
 199 However, using  $normalize_1$ , the free variable  $y$  is captured:

```
200      normalize1 ((λx. λy. x) y)
201    ≡ normalize1 (λy. [y])
202    ≡ λy. normalize1 [y]
203    ≡ λy. y
```

205 The next section discusses a more general substitution strategy due to Berkling and Fehr [7]  
 206 which does not have this limitation, which does not rename variables, and which is more  
 207 efficient than the renaming based approach in § 2.2.

### 208 3 Berkling-Fehr Substitution

209 Motivated by how to implement a functional programming language based on Church's  
 210 λ-calculus [10], Berkling and Fehr [7] introduced a modified version of Church's λ-calculus  
 211 which uses a different kind of name binding and substitution. The key idea is to use a special  
 212 operator ( $\#$ ) that acts on variables to neutralize the effect of one  $\lambda$  binding. For example, in  
 213 the term  $\lambda x. \lambda x. \#x$  the sub-term  $\#x$  is a variable that references the *outermost* binding of  
 214  $x$ , whereas in  $\lambda x. \lambda y. \#x$  the sub-term  $\#x$  is a free variable.

215 Berkling and Fehr's  $\#$  operator is related to De Bruijn indices [14] insofar as  $\#^n x$  acts  
 216 like an index that tells us to move  $n$  binders of  $x$  outwards. Indeed, if we were to restrict  
 217 programs in Berkling and Fehr's calculus to use exactly one name, Berkling-Fehr substitution  
 218 coincides with De Bruijn substitution. However, whereas De Bruijn indices can be notoriously  
 219 difficult for humans to read (especially for beginners), Berkling-Fehr uses named variables  
 220 such that indices only appear for substitutions that would otherwise have variable capture.  
 221 This makes Berkling-Fehr variables easier to read for humans.

222 The definitions of shifting and substitution which we summarize in this section are taken  
 223 from the work Berkling and Fehr [7] with virtually no changes. However, the language we  
 224 implement is slightly different: they implement a modified λ-calculus with a call-by-name  
 225 semantics, whereas we implement the same call-by-value language as in § 2. Our purpose of  
 226 replicating their work is two-fold: to increase the awareness of Berkling-Fehr substitution and  
 227 its seemingly nice properties, and to facilitate comparison with the renamingless approach  
 228 we presented in § 2.3.

#### 229 3.1 Interpreting Open Expressions with Berkling-Fehr Substitution

230 Below (left) is a syntax for λ expressions similarly to earlier, but now with Berkling-Fehr  
 231 indices (right) instead of variables, where  $Nat$  is the type of natural numbers:

<pre> data Expr<sub>2</sub>   = Lam<sub>2</sub> String Expr<sub>2</sub>     Var<sub>2</sub> Index     App<sub>2</sub> Expr<sub>2</sub> Expr<sub>2</sub>     Num<sub>2</sub> Int </pre>		<pre> data Index = I { depth :: Nat, name :: String } </pre>
--	--	--

233 Here the (record) data constructor  $I\ n\ x$  corresponds to an  $n$ -ary application of the special  
 234  $\#$  operator to the name  $x$ ; i.e.,  $\#^n x$ . We will refer to the  $n$  in  $I\ n\ x$  as the *depth* of an  
 235 index. As discussed above, a Berkling-Fehr index is similar to a De Bruijn index except that  
 236 whereas a De Bruijn index tells us how many scopes to move out in order to locate a binder,

237 a Berkling-Fehr index tells us how many scopes *that bind the same name* to move out in order  
 238 to locate a binder. In what follows, we will sometimes use  $\lambda$  notation as informal syntactic  
 239 sugar for the constructors in Haskell above. When doing so, we use “naked” variables  $x$  as  
 240 informal syntactic sugar for a variable at depth 0; i.e.,  $\text{Var}_2 (I\ 0\ x)$ .

241 To define Berkling-Fehr substitution, we need a notion of *shifting*. Shifting is used when  
 242 we propagate a substitution, say  $x \mapsto e$  where  $x$  is a name and  $e$  is an expression, under a  
 243 binder  $y$ . To this end, a shift increments the depth of all free occurrences of  $y$  in  $s$  by one.  
 244 Such shifting guarantees that free occurrences of  $y$  in  $s$  are not accidentally captured.

```

245 shift :: Index → Expr2 → Expr2
246 shift i (Lam2 x e) | name i ≡ x      = Lam2 x (shift (inc i) e)
247                   | otherwise         = Lam2 x (shift i e)
248 shift i (Var2 i') | name i ≡ name i'
249                   | depth i ≤ depth i' = Var2 (inc i')
250                   | otherwise         = Var2 i'
251 shift i (App2 e1 e2) = App2 (shift i e1) (shift i e2)
252 shift _ (Num2 z)     = Num2 z

```

253 The *shift* function binds an index as its first argument. The name of this index (e.g.,  $x$ )  
 254 denotes the name to be shifted. The depth of the index denotes the *cut-off* for the shift;  
 255 i.e., how many  $\#$ 's an  $x$  must at least be prefixed by before it is a free variable reference  
 256 to  $x$ . For example, say we wish to shift all free references to  $x$  in the term  $\lambda x. x (\#x)$ . We  
 257 should only shift  $\#x$ , not  $x$ , since  $x$  references the locally  $\lambda$  bound  $x$ . For this reason, the  
 258 shift function uses a cut-off which is incremented when we move under binders by the same  
 259 name as we are trying to shift. For example:

```

260 shift x (λx. x (#x))
261 ≡ λx. (shift (#x) x) (shift (#x) (#x))
262 ≡ λx. x (##x)
263

```

264 The Berkling-Fehr substitution function  $\text{subst}_2$  applies shifting to avoid variable capture  
 265 when propagating substitutions under  $\lambda$  binders:

```

266 subst2 :: Index → Expr2 → Expr2 → Expr2
267 subst2 i s (Lam2 x e) | name i ≡ x = Lam2 x (subst2 (inc i) (shift (I 0 x) s) e)
268                   | otherwise     = Lam2 x (subst2 i (shift (I 0 x) s) e)
269 subst2 i s (Var2 i') | i ≡ i'      = s
270                   | otherwise     = Var2 i'
271 subst2 i s (App2 e1 e2) = App2 (subst2 i s e1) (subst2 i s e2)
272 subst2 _ (Num2 z)      = Num2 z

```

273 To interpret an  $\text{Expr}_2$  application  $e_1\ e_2$ , we first interpret  $e_1$  to a function  $\lambda x. e$ , and then  
 274 substitute  $x$  in the body  $e$ , such that occurrences of  $x$  at a higher depth are left untouched.  
 275 But after we have substituted the bound occurrences of  $x$  in  $e$ , the depth of the remaining  
 276 occurrences of  $x$  in  $e$  need to be decremented. To this end, we use an *unshift* function which  
 277 decrements the depth of a given name, modulo a cut-off which now tells us what depth a  
 278 name has to strictly be larger than in order for it to be a free variable to be unshifted:

```

279 unshift :: Index → Expr2 → Expr2
280 unshift i (Lam2 x e) | name i ≡ x      = Lam2 x (unshift (inc i) e)

```

$$\begin{aligned}
& \text{unshift } i \text{ (Var}_2 \text{ } i') \quad \begin{cases} | \text{ otherwise} & = \text{Lam}_2 \text{ } x \text{ (unshift } i \text{ } e) \\ | \text{ name } i \equiv \text{name } i' \\ & \wedge \text{ depth } i < \text{depth } i' = \text{Var}_2 \text{ (dec } i') \\ | \text{ otherwise} & = \text{Var}_2 \text{ } i' \end{cases} \\
& \text{unshift } i \text{ (App}_2 \text{ } t1 \text{ } t2) = \text{App}_2 \text{ (unshift } i \text{ } t1) \text{ (unshift } i \text{ } t2) \\
& \text{unshift } - \text{ (Num}_2 \text{ } z) = \text{Num}_2 \text{ } z
\end{aligned}$$

Using *unshift*, we can now implement an interpreter that does evaluation under  $\lambda$ s and that uses capture-avoiding substitution:

$$\begin{aligned}
& \text{normalize}_2 :: \text{Expr}_2 \rightarrow \text{Expr}_2 \\
& \text{normalize}_2 \text{ (Lam}_2 \text{ } x \text{ } e) = \text{Lam}_2 \text{ } x \text{ (normalize}_2 \text{ } e) \\
& \text{normalize}_2 \text{ (Var}_2 \text{ } i) = \text{Var}_2 \text{ } i \\
& \text{normalize}_2 \text{ (App}_2 \text{ } e_1 \text{ } e_2) = \text{case normalize}_2 \text{ } e_1 \text{ of} \\
& \quad \text{Lam}_2 \text{ } x \text{ } e \rightarrow \text{unshift (I 0 } x) \text{ (normalize}_2 \text{ (subst}_2 \text{ (I 0 } x) \text{ (normalize}_2 \text{ } e_2) \text{ } e))} \\
& \quad e'_1 \rightarrow \text{App}_2 \text{ } e'_1 \text{ (normalize}_2 \text{ } e_2) \\
& \text{normalize}_2 \text{ (Num}_2 \text{ } z) = \text{Num}_2 \text{ } z
\end{aligned}$$

For example, the problematic program from § 2.4 now yields a result with a free variable, as expected:

$$\text{normalize}_2 ((\lambda x. \lambda y. x) y) \equiv \lambda y. \#y$$

### 3.2 Relation to Renamingless Substitution

On the surface, the techniques involved in Berkling-Fehr substitution and our renamingless substitution strategy from § 2 seem rather different. A common point between the two is that they avoid renaming by strategically closing off certain variables to protect them from substitutions from lexically closer binders, and strategically reopening those variables to substitutions coming from lexically distant binders.

The renamingless substitution strategy achieves this by using a syntactic and rather coarse-grained discipline which closes entire sub-branches over all possible substitutions. When the interpreter reaches a closed sub-expression, it is re-opened. As discussed, this discipline works well for languages that do not perform evaluation under binders. While we demonstrated the technique using a call-by-value language in § 2, the technique is equally applicable to call-by-name interpretation. But not for languages that perform evaluation under binders.

Berkling-Fehr substitution uses a more fine-grained approach to strategically close off variables to protect them from substitutions from lexically closer binders, by shifting free occurrences of variables when moving under a binder. When a binder is eliminated, terms are unshifted. This fine-grained approach is not subject to the same limitations as the renamingless approach from § 2.3. Indeed, in their paper, Berkling and Fehr [7] prove that their notion of substitution and their modified  $\lambda$ -calculus is consistent with Church's  $\lambda$  calculus. Since shifting and unshifting requires more recursion over terms than the simpler renamingless approach from § 2, Berkling-Fehr substitution is less efficient. However, it is still more efficient than the renaming approach discussed in § 2.2.

As discussed, Berkling-Fehr substitution is closely related to De Bruijn indices, the main difference being that Berkling-Fehr use names and are more readable. To work around the readability issue with De Bruijn indices, one might also combine a named and De Bruijn approach where variable nodes comprise *both* a name *and* a De Bruijn index. But that leaves

the question of how to disambiguate programs with ambiguous name. For example, how do we represent the Berkling-Fehr indexed expression  $\lambda x. \lambda x. \#x$  using this hypothetical combined De Bruijn/named approach? Berkling-Fehr indices seem to strike an attractive balance between being practical and readable.

## 4 Related Work

In this paper we explored two techniques for capture avoiding substitution that avoids renaming, for the purpose of implementing static name binding in languages with  $\lambda$ s. The topic of evaluating  $\lambda$  expressions has a long and rich history. Summarizing it all is beyond the scope of this paper; for overviews see, e.g., the works of Barendregt [6] or Cardone and Hindley [8]. We discuss a few of the papers that are most closely related to the techniques we have described.

In their formalization of  $\lambda$  calculus and type theory, McKinna and Pollack [17] consider a system that uses named substitution without renaming, for a particular notion of open terms. They consider a syntax that distinguishes two classes of names: *parameters* and *variables*. *Variable substitution* does not affect parameters, and *parameter substitution* does not affect variables. Their notion of variable substitution is defined for terms that are *variable-closed*, but which may be *parameter-open*. Thus, by encoding free variables as parameters, their system can be used to compute with open terms. However, syntactically distinguishing free variables this way seems to presupposes a static binding analysis. The approach we discussed in § 2.3 does not presuppose such static analysis.

Our paper considers how to interpret open terms. There exist several calculi in the literature for evaluating open terms. Accatolli and Guerrieri [2] gives an overview of several of these calculi for *open call-by-value*, which is the class of languages that the interpreters in § 2 and § 3 interpret. In their paper, Accatolli and Guerrieri focus on the meta-theory of these calculi. For their meta-theoretical study they rely on an unspecified notion of capture-avoiding substitution. In this paper, we explore how to define such capture-avoiding substitution in a way that does not perform renaming. While the meta-theory of Berkling-Fehr substitution has been studied [7], the meta-theory of the substitution strategy in § 2.3 remains an open question.

## 5 Conclusion

We have discussed two techniques for implementing capture avoiding substitution in definitional interpreters in a way that does not require renaming of bound variables. One of the techniques relies on a coarse-grained but simple discipline for closing terms, is known to not support interpretation strategies that evaluate under binders, and has (to the best of our knowledge) not been studied meta-theoretically. The other technique is an existing technique from the literature. While this technique is less efficient, it is more fine-grained and so does not subject to the same limitations as the first technique. It also has a well-established meta-theory. Neither of the two techniques seem to be widely known or at least not widely applied. With this work, we hope to increase awareness of these techniques.
